Figure 1: Overview: (a): A position-correcting tool. The device consists of a frame and a tool (in this case a router) mounted within that frame. The frame is positioned manually by the user. A camera on the frame (top right in the figure) is used to determine the frame’s location. The device can adjust the position of the tool within the frame to correct for error in the user’s coarse positioning. (b): To follow a complex path, the user need only move the frame in a rough approximation of the path. In this example, the dotted blue line shows the path that the tool would take if its position were not adjusted; the black line is its actual path. (c): An example of a shape cut out of wood using this tool.

Abstract

Many kinds of digital fabrication are accomplished by precisely moving a tool along a digitally-specified path. This precise motion is typically accomplished fully automatically using a computer-controlled multi-axis stage. With that approach, one can only create objects smaller than the positioning stage, and large stages can be quite expensive. We propose a new approach to precise positioning of a tool that combines manual and automatic positioning: in our approach, the user coarsely positions a frame containing the tool in an approximation of the desired path, while the device tracks the frame’s location and adjusts the position of the tool within the frame to correct the user’s positioning error in real time. Because the automatic positioning need only cover the range of the human’s positioning error, this frame can be small and inexpensive, and because the human has unlimited range, such a frame can be used to precisely position tools over an unlimited range.

1 Introduction

Personal digital fabrication endeavors to bridge the gap between computer graphics and the real world, turning virtual models into physical objects. Novel software modeling allows users to create unique objects of their own design, e.g. [Mori and Igarashi 2007; Killian et al. 2008; Lau et al. 2011; Saul et al. 2011], which can then be fabricated using 2D devices such as laser or water jet cutters, or 3D devices such as 3D printers and computer numerical control (CNC) mills. While rapid prototyping machines are dropping in price, affordable tools have severe size limitations because of the expense of a precise and long-range positioning system. As an illustration, a 2’ × 1.5’ ShopBot CNC mill costs approximately $6,000, while a 5’ × 8’ ShopBot mill costs over $20,000 [ShopBot Tools].

We aim to reduce the cost of digital fabrication for the domain of 2D shapes while simultaneously removing constraints on range. Our central idea is to use a hybrid approach to positioning where a human provides range while a tool with a cheap short-range position adjustment enables precision. Given an input 2D digital plan such as the outline of a shape, the user manually moves a frame containing a tool in a rough approximation of the desired plan. The frame tracks its location and can adjust the position of the tool within the frame over a small range to correct the human’s coarse positioning, keeping the tool exactly on the plan (Figure 1). A variety of tools can be positioned in this manner, including but not limited to a router (which spins a sharp bit to cut through wood, plastic, or sheet metal in an omnidirectional manner) to cut shapes, a vinyl cutter to make signs, and a pen to plot designs.

In this approach, the core challenges are localization (determining the current position of the tool) and actuation (correcting the tool’s position). For localization, we use computer vision and special markers placed on the material. For actuation, we present a two-axis linkage that can adjust the position of the tool within the frame. We also describe an interface for guiding the user using a screen on the frame, which illustrates the tool’s current position relative...
to the plan. We show an example of a device (Figure 1), measuring roughly 13" x 10" x 9", that uses our approach and can be fitted with a router or a vinyl cutter, and show results that can be achieved with these tools when they are positioned with our computer-augmented approach.

2 Related Work

Recent work on personal digital fabrication has yielded interfaces that integrate fabrication considerations with design, allowing fabrication-conscious design of a variety of material and object types such as plush toys [Mori and Igarashi 2007], chairs [Saul et al. 2011], furniture [Lau et al. 2011], shapes made out of a single folded piece of material [Kilian et al. 2008], and panelized buildings [Eigensatz et al. 2010]. Other papers explore how to generate designs with desired physical properties, such as deformation characteristics [Bickel et al. 2010], appearance under directed illumination [Alexa and Matusik 2010], and subsurface scattering [Dong et al. 2010; Hasan et al. 2010].

When it comes to fabricating objects from these designs, the most widely used devices are 3D printers, laser cutters, and CNC milling machines. Recently, a variety of efforts growing out of the DIY community have sought to reduce the cost of 3D printers [MakerBot Industries; Drumm 2011; Selis et al. 2009] and CNC mills [Hokanson and Reilly; Kelly]. These projects typically provide relatively cheap kits for entry-level devices. However, as with professional models, positioning is done with a multi-axis stage, and the trade-off between cost and range remains.

Our computer-augmented positioning approach removes the limitation on range of traditional gantry-based positioning technologies. To do so, it relies on accurately detecting the position of the frame in real time. A variety of approaches to real-time localization have been employed over the years, from global-scale GPS [Gettig 1999] to local-scale systems based on radio and ultrasonic signals [Priyantha et al. 2000]; an overview is given in a survey by Welch and Foxlin (2002).

Our approach to localization is based on computer vision. Computer vision has been widely used for position tracking in the context of motion capture (see Moeslund et al. (2006) for a survey). These setups typically use stationary cameras tracking a moving object, though recently Shiratori et al. (2011) proposed a system in which cameras are placed on the human and track the environment. In our approach, the camera is on the tool and tracks the material over which it moves, first stitching frames together to make a map of the material (see Zitova and Flusser (2003) and Szeliski (2006) for surveys of image registration and stitching techniques) and then using that map to perform localization. This approach has been used before, with some differences, in a recent new peripheral, LG’s LSM-100 scanner mouse (LG; Zahnert et al. 2010), which is a mouse that can scan a document it is passed over. Our implementation differs from theirs in that we use only a camera (no optical mice), capture a wider area of the material in each frame, and use high-contrast markers placed on the material to allow capture of untextured materials.

Computer vision has been applied to CNC manufacturing, for example to monitor for mistakes [Al-Kindi et al. 1993], or to precisely align a tool path to a piece of material [Techno CNC Router Systems]. These approaches, however, do not re-imagine the fundamental approach or form factor of a table-based, fully automatically-positioned CNC device. A hybrid approach has been taken in the case of computer-assisted surgical devices [Kragic et al. 2005; Mako Surgical]. For example by using a robot to recreate a manual tool motion at a smaller scale for microsurgery. However, the motivation in these cases is to "take advantage of robotic speed and precision, but avoid the difficulties of full autonomy by retaining the human ‘in the loop’ for essential decision making and/or physical guidance" [Kragic et al. 2005]. By comparison, our goal is to leverage the human’s mechanical range, rather than decision making power or guidance, to enable a new form factor and approach to a task that is currently fully automated.

3 Localization

To keep the tool on the plan as closely as possible, the tool must detect its current position accurately, robustly, and with low latency.

We considered a variety of localization systems, eventually settling on a simple computer vision-based approach, in which a camera on the frame of the device tracks high-contrast markers placed in an arbitrary pattern on the material. A map of the material (Figure 2) is first built by passing the device back and forth over the material to be cut; then, images from the camera are compared to this map to determine the device’s location. This approach was chosen for a variety of reasons: it can achieve very high accuracy; it always remains calibrated to the material, as the markers are on the material itself (as opposed to external beacons, which can become uncalibrated); it does not require excessive setup; the hardware required is relatively inexpensive, and it can be implemented using standard computer vision techniques. Building the map is fast and easy.

We considered using the camera to track just motion, as in an optical mouse, but this approach would be subject to drift. An alternative would be to draw the plan on the material itself, e.g. with a pencil, and then track that, but that would require additional work on the part of the user and could introduce error.

3.1 High-contrast markers

We leverage specially-printed tape marked with high-contrast patterns to make it possible to track materials that have no visual features of their own (such as sheet metal or plastic) and to increase robustness under varying lighting conditions. This tape is applied before map-making, in any pattern so long as some tape is visible from every position that the device will move to, and can be removed when the job is complete. The tape consists of many Quick Response (QR) code-like markers [Denso-Wave Incorporated] in a row, each consisting of an easily-detectable box-within-box pat-
We use a simple method to stitch images together. Each frame's position is added to the list of detected markers. Once the location of the frame is known, the tool must be repositioned within the frame to keep it on the plan. This task can be broken down into the control challenge of determining where within the frame to move (as there are usually many possible positions that lie on the plan) and the mechanical engineering challenge of building an accurate, responsive, and low-cost position-adjusting actuation system.

The range of our positioning linkage was determined by first attempting to move the frame along a 2D plan as closely as possible by hand. We found that when provided with accurate location information relative to the plan a user can keep the tool within 1/8" of the plan, even when cutting wood. Having accurate location information allows for greater precision than normal freehand positioning. To allow for a safety margin and increase ease of use, we doubled this value to arrive at the goal of being able to correct errors up to 1/4" (i.e. having a range circle with a 0.25" diameter).
4.1 Actuation system

The actuation system need only support a small range of motion, as it need only correct the coarse positioning done by the human. This affords the possibility of using a very different design for the positioning system than the multi-axis stage employed by traditional rapid prototyping machines.

Our major mechanical departure from traditional rapid prototyping machines is that we use eccentrics, rather than linear stages, to convert the rotational motion of the motors into linear motion. Eccentrics are circular disks rotating around an off-center shaft. As they are rotated, they produce linear motion in a collar wrapped around the disk. Eccentrics are able to maintain the same low-backlash accuracy of a precision linear stage while being much cheaper. For this, they sacrifice range. However, a linear displacement range of 1/2" is well within the capabilities of an eccentric.

Our design (Figure 4) consists of two eccentrics mounted to the frame and connected to a stage that can slide on its base. The eccentrics are rotated by stepper motors, and by rotating them the stage can be moved within the frame. To properly constrain the stage, one eccentric is connected directly to the stage while the other is connected both by a coupling and a hinge.

This linkage design results in a nonlinear relationship between eccentric orientation and stage position: as the tool approaches the edge of its range, increasingly large rotations are necessary to move the stage a fixed amount. We limit stage displacement to ~95% of the maximum range to cut out the positions with extreme nonlinearity. This linkage design also permits backdriving, in that forces acting on the tool can cause the cam to rotate away from their target positions; however, we found that the stepper motors we use (62 oz-in holding torque) are sufficiently powerful to preclude backdriving, even in the presence of significant material forces.

4.2 Following a plan

As the user moves the frame, the device must ensure that the tool stays on the plan. To do this, the path that is to be followed must be first computed (which may not be the same as the plan); then, every frame, given the frame’s position, the tool’s position within the frame, and the plan, the device must determine where to move the tool within the frame.

For the applications we focus on – routing and vinyl cutting – the user generally wishes to cut a shape out of a piece of material. This means that there will be some areas of the material that are outside the target shape, and which may be cut freely (which we call "exterior material"), while other areas lie inside the target shape and must not be cut ("interior material"). To allow for this distinction, we define a plan as consisting of polygons, which have defined interiors, rather than simply as paths.

In applications such as vinyl cutting, the tool should follow the border of the interior material as closely as possible. When routing, however, the size of the cutting bit must be taken into account, and the tool should move along a path offset from the interior material by the radius of the bit to leave the actual cut shape as close as possible to the specified plan. We provide an option to set the diameter of the cutting bit and offset the plan polygons accordingly.

We propose two different strategies for moving the tool to keep it on the plan, and will show how each of these is appropriate for a different class of applications.

4.2.1 Constant-speed motion

In the simpler strategy, the tool is moved through the material at as close to a constant rate as possible. This strategy is useful for applications such as routing, in which the material may offer resistance if the tool is moved too quickly and may burn if the tool is moved too slowly.

In this approach, the user decides only what polygon to follow and when to start motion. Thereafter, the software drives the tool around that polygon at a constant rate; the rate is a setting the user can tune (0.2" per second by default). While the tool is moving, the user moves the frame to keep the tool near the center of its range, ensuring that the tool can continue its constant-speed motion without reaching the end of its range. If the tool does reach the end of its range, it must stop until the user catches up.
4.2.2 Freeform motion

In the second strategy, the user moves the frame around the plan freely, and the device tries to keep the tool at the point on the plan that most "makes sense" given the user's positioning of the frame. This approach is suitable to applications such as plotting or vinyl cutting in which there is negligible material resistance and no need to move at a constant rate. It can be used to cut shapes much faster than the constant-speed strategy, as the user can slow down only when necessary, such as at sharp turns. In this mode, the amount of error in the tool's positioning is related more to the overall speed of the device, but rather to the speed at which the device is moving away from the plan; roughly speaking, the user should not diverge from the plan faster than 0.2" per second. The point that the tool is moved to is, generally speaking, the closest point on the border of a plan polygon to the center of the tool's range. However, several considerations make the determination of the path to get to this point complicated. First, the tool should never move through interior material, even if the shortest path from its current position to the target position goes through it. Second, the tool should seek to follow the border of the interior material even when a shorter direct route is possible through exterior material, to avoid skipping over features of the plan.

We aim to account for these considerations while also maximizing the predictability of the tool's motion. We propose a simple strategy in which four possible paths are computed each frame, ranking from most desirable to least desirable, and the most desirable path that is feasible is followed. All seek to move the tool to the target position, which is the closest point on the border of a plan polygon to the center of the tool's range, or to the center of the tool's range itself if the target position is not reachable. These paths, illustrated in Figure 5, are:

1. The path that goes from the tool's position to the nearest point on the border of a polygon, and then walks along the border of that polygon to the target position in whichever direction is shorter. This path is infeasible if it leaves the tool's range or if the target position is on the border of a polygon other than the polygon closest to the tool's position.

2. The path that goes from the tool's position to the nearest exterior material (if it is in the interior material) and then in a straight line to the target position. This path is infeasible if the nearest exterior material is outside the range or the straight line segment passes through interior material.

3. The path that goes from the tool's position to the nearest exterior material (if it is in the interior material) and then in a straight line to the center of the tool's range, stopping whenever interior material is encountered. This path is infeasible if the nearest exterior material lies outside the range of the tool.

4. Don't move. This path is always feasible.

5 Using the tool

The use of the device proceeds as follows: the user places marker tape on the material; the user scans the material; the user registers a plan onto the scanned map of the material; the user uses the device to follow the plan. The user roughly follows the shape of the plan, and the positioning linkage moves the tool to keep it exactly on the plan. In principle, the tool can follow any 2D path. In the application of routing, this means that it can cut out any 2D shape in a single pass, or more complex 2.5D (heightmap) shapes using multiple passes at different depths. Multiple passes can be taken with or without adjusting the plan between passes. For example, we have used multiple passes with the same plan to cut through material thicker than can be cut in a single pass; we have also used different plans to engrave text to a shallow depth on a piece that is then cut out.

5.1 User interface

The user is helped to follow the plan by a display shown on a screen on the tool. This display shows the position of the tool relative to the plan (see Figure 6). In theory, the user's task is to keep the center of the router's motion range as close to the plan as possible. In practice, the user may deviate by as much as the radius of the router's adjustment range.
Figure 8: Range: A full-size vinyl cutout of a human silhouette (5'6" tall), with original.

We found that this simple interface was able to effectively guide the user in every case we tested. It was easy to follow complex shapes, and thanks to showing the area already cut by the tool, it was possible to interrupt cutting and then return to the correct place.

6 Results

We built a device (Figure 1) that implements the position-correcting system described above. The aluminum base was cut on a CNC mill, while the plastic parts were made with a 3D printer. The device that we built can be mounted with a router or vinyl cutter, and can follow any 2D plan. Figures 1 and 7 show shapes cut out of wood, plastic, paperboard, and sheet metal. Figure 8 demonstrates the range of the device with a full-size vinyl cutout of a human silhouette. Figure 9 shows an example of a cut shape with high-resolution details.

We empirically tested the fidelity of shape reproduction by plotting a complex pattern with a pen mounted as the tool, scanning the result, and measuring deviation from the digital plan (Figure 10). The shape was plotted 6" wide. We fitted a curve to the scanned plot, aligned the plan to that curve, and measured deviation from evenly-sampled points along the drawn shape curve to the nearest point on the plan. The average error was 0.009", with a maximum error of 0.023". The error was small enough that the aligned design always fell within the width of the pen stroke.

7 Conclusion and future work

We have demonstrated a computer-augmented positioning system that avoids the cost-versus-range tension that currently affects rapid prototyping devices, and shown a tool using this approach that combines the unlimited range of a human operator with the accuracy of a computerized positioning system. This device incorporates a computer vision-based system for localization and a specially designed low-cost linkage that can be used to adjust the position of a tool within the device’s frame. We have shown how this device can be used with a router and a vinyl cutter to accurately fabricate objects from digital plans.

In future work, we would like to explore applying this type of computer-augmented positioning to a variety of other tools and device form factors. It may also be useful to add automatic Z-axis control to the tool for certain applications, such as when the plan consists of many disconnected subparts. We also wish to explore the possibility of capturing the map using a separate camera looking over the work area, as this would speed up mapmaking and may be useful in cases where many sheets of material are cut in the same physical workspace.
